Abstract

We propose a novel method for the creation of spatially-separated spin entanglement by means of adiabatic passage of an external gate voltage in a triple quantum dot system.

Key words: Spin entanglement, quantum dot, adiabatic passage

Entanglement is of great interest in quantum computation[1, 2], quantum teleportation[3], and fundamental tests of quantum mechanics [4, 5]. Designing and realizing quantum entanglement is extremely challenging due to the intrinsic decoherence, which is caused by the uncontrollable coupling with environmental degrees of freedom. A variety of physical systems have been chosen to investigate the controlled, entangled states. Among these are trapped ions[6], spins in nuclear magnetic resonance (NMR)[7], cavity-quantum-electrodynamics systems[8], Josephson junctions[9], and quantum dots (QDs)[10].

Due to the potential scalability and long decoherence times of the electron spins, the solid-state quantum dot (QD) system has been extensively studied for realization of a quantum computer both from theory and experiment[11]. How to extract entangled particles into spatially-separated channels is an important issue. Costa and Bose[12] have shown how a QD can function as an effective beam splitter to entangle two conduction electrons. Oliver *et al.*[13] have considered a single-level QD with one input and two output leads. Via a detailed calculation of the transition amplitudes in the T matrix formalism, they have shown that a nonlocal spin-singlet state at the output leads may be produced by the Coulomb interaction. Very recently, Saraga and Loss[14] have proposed a novel spin entangler consisting of three coupled quantum dots. They have showed that such a device can separate two entangled electrons and extract them into two distinct channels.

In this paper we propose a means to generate spatially-separated spin-entangled electron pair by using an adiabatic passage method. Adiabatic passage is a powerful tool for manipulating a quantum system from an initial state to a target state and has been extensively used recently to create coherent superpositions of atomic states[15] and photon states[16]. Until now very little efforts have been devoted to implement adiabatic passage with artificial atom—i.e., QD system—although there has been important progress in manipulating quantum states of the QD by using an electric or magnetic field. Such examples are optically triggered single-electron turnstile[17] and manipulation of dot spin dynamics[11]. Here we illustrate how to implement quantum state transfer in a QD system by use of adiabatic passage of one single parameter of gate voltage. In contrast to real atom system, the QD system allows for a precise control over the energy level structure. In some sense the entangler behaves like a quantum tweezer[18], which picks up two electrons from the source lead, entangles and adiabatically transfers them into the two output channels. We notice that adiabatic control of the single-particle wavefunction was recently suggested for current

transport through a triple QD system[20].

As in Ref.[14], the entangler, as schematically shown in Fig. 1(a), is a triple QD system in the Coulomb blockade regime. The central dot is connected to an input lead, while the left and right dots are coupled to two output leads. We consider the case that there are *two* excess electrons in the central dot. These two electrons are from the input lead and their ground state is a spin-singlet state. Then the aim of the entangler is to extract the singlet from the central dot, by transferring one electron to the left dot and the other one to the right dot, and finally transport them *simultaneously* into the output ports. The final step can be easily achieved via the single-particle tunneling mechanism when the two electrons are present in the left and right dots. Therefore the most important step is how to transfer the two electrons into the two side dots simultaneously in a controllable way, which is our goal in this paper. By adiabatic manipulation of the gate voltage V_g applied on the central dot, we show that the two spin-singlet electrons localized initially in the central dot can be transferred into the two side dots simultaneously, with each dot only being occupied by one electron [schematically shown in Fig. 1(b)]. The evolution is rather around *one* avoided crossing in the eigenenergy spectrum than along the ground state manifold which is characterized by a series of Coulomb-induced avoided crossings. Typical non-adiabatic tunneling mechanism, which will lead to a leakage out of the target state, is greatly suppressed by adiabatic passage. Thus the spatially-separated spin-entangled state builds up robustly. Our proposal is very simple and easy to implement in experiments. The only variable parameter is the single-particle energy level of the central dot, which can be conveniently controlled by the gate voltage applied on it.

Accounting only for the occupation of the lowest single-particle state of each dot, the system is described by a three-site Hubbard model

$$H(t) = \varepsilon_s(d_{L\sigma}^+ d_{L\sigma} + d_{R\sigma}^+ d_{R\sigma}) + \varepsilon_c d_{C\sigma}^+ d_{C\sigma} - w \sum_{\alpha=L,R\sigma} (d_{\alpha\sigma}^+ d_{C\sigma} + \text{H.c.}) \quad (1)$$

$$+ U_s(n_{L\uparrow} n_{L\downarrow} + n_{R\uparrow} n_{R\downarrow}) + U_c n_{C\uparrow} n_{C\downarrow},$$

where $d_{C\sigma}^+$ or $d_{L\sigma}^+$ ($d_{R\sigma}^+$) creates a spin- σ electron on the central or left (right) dot. ε_s and ε_c are the on-site orbital energies for the side and central dots, respectively. U_s is the Coulomb repulsion of the side dots, while U_c is the same for the central dot. w denotes hopping amplitude between the side dots and central dot. We will see below that U_s has no relevance to the problem since the states for which the two electrons occupy the same left or right dot

are unwanted states and can be eliminated from the evolution of the system. The initial state—i.e., two electrons are localized in the central dot—is a spin-singlet state, as has been verified in experiments[19]. Since there are no spin-dependent terms in (1), the subsequent system evolution is confined to the spin-singlet states. In the spin-singlet subspace, the two-particle basis is given by

$$|S^1\rangle = LL = d_{L\downarrow}^+ d_{L\uparrow}^+ |0\rangle, \quad (2a)$$

$$|S^2\rangle = LC = \frac{1}{\sqrt{2}}(d_{C\downarrow}^+ d_{L\uparrow}^+ - d_{C\uparrow}^+ d_{L\downarrow}^+) |0\rangle, \quad (2b)$$

$$|S^3\rangle = CC = d_{C\downarrow}^+ d_{C\uparrow}^+ |0\rangle, \quad (2c)$$

$$|S^4\rangle = RC = \frac{1}{\sqrt{2}}(d_{R\downarrow}^+ d_{C\uparrow}^+ - d_{R\uparrow}^+ d_{C\downarrow}^+) |0\rangle, \quad (2d)$$

$$|S^5\rangle = RR = d_{R\downarrow}^+ d_{R\uparrow}^+ |0\rangle, \quad (2e)$$

$$|S^6\rangle = LR = \frac{1}{\sqrt{2}}(d_{L\downarrow}^+ d_{R\uparrow}^+ - d_{L\uparrow}^+ d_{R\downarrow}^+) |0\rangle, \quad (2f)$$

where $|0\rangle$ is the empty state with no excess electrons on the entangler. We set the zero of the on-site energy as $\varepsilon_s = 0$. Thus in the following ε_c is defined with respect to ε_s . In the spin-singlet subspace, the Hamiltonian (1) is rewritten as a 6×6 matrix

$$H = \begin{pmatrix} U_s & \sqrt{2}w & 0 & 0 & 0 & 0 \\ \sqrt{2}w & \varepsilon_c & \sqrt{2}w & 0 & 0 & w \\ 0 & \sqrt{2}w & 2\varepsilon_c + U_c & \sqrt{2}w & 0 & 0 \\ 0 & 0 & \sqrt{2}w & \varepsilon_c & \sqrt{2}w & w \\ 0 & 0 & 0 & \sqrt{2}w & U_s & 0 \\ 0 & w & 0 & w & 0 & 0 \end{pmatrix}. \quad (3)$$

The gate voltage is applied on the central dot to control ε_c . The starting state is CC and the target state is spatially-separated state LR . Given an initial state $|\Psi(0)\rangle$, the consequent time evolution of the state is given by the Schrödinger equation

$$i \frac{d}{dt} |\Psi(t)\rangle = H |\Psi(t)\rangle. \quad (4)$$

The state $|\Psi(t)\rangle$ is expressed as a superposition of the six basis states

$$|\Psi(t)\rangle = \sum_k c_k(t) |S^k\rangle. \quad (5)$$

The probability of finding target state LR is given by $\rho_{LR}(t) = |c_6(t)|^2$.

In the absence of hopping term ($w = 0$), the Hamiltonian (3) is diagonal and the basis states are exact eigenstates. For illustration, the eigen-energies are shown in Fig. 2(a) as a function of ε_c , which is tuned by external gate voltage V_g . One can see that at

$$\varepsilon_c = -U_c/2, \quad (6)$$

the eigenstates CC and LR are degenerate. There are also the other three level crossings, which have no relevance to this paper. The presence of the hopping term w opens up energy gaps at the crossings [see Fig. 2(b)], which implies strong mixing between the corresponding hopping-free states. Meanwhile, the location of the avoided crossing between CC and LR states deviates from the expression in Eq. (3) [see the inset of Fig. 2(b)]. To illustrate the system dynamics at this avoided crossing, starting from the initial state CC , we plot in Fig. 3(a) (solid lines) time evolution of the probability of finding states $|S^k\rangle$ ($k = 1, \dots, 6$). One can see that the dynamics is dominated by a resonant oscillation between CC and LR , while populations of other two-particle states are negligible. If the gate voltage that controls ε_c is suddenly switched to another value at time that the occupation probability of state LR is unity, then the two electrons will cease oscillation and remain in the target state LR , as shown in Fig. 3(b).

To find an analytical expression for the location of the avoided crossing in the inset of Fig. 2(b), and the resonant oscillation period in Fig. 3, we present a two-state approximation by adiabatically eliminating contributions of the other states to the dynamics. From the expression of Hamiltonian (3) one can see that the states CC and LR only couple with the states LC and RC in which one electron occupies the central dot and the other on one side dot. Because population of the states LC and RC remains very small during time evolution as shown in Fig. 3, we can approximate $c_2(t)$ and $c_4(t)$ in Eq. (5) to the first order of the hopping term:

$$c_2(t) = -\frac{\sqrt{2}w}{\varepsilon_c} c_3(t) - \frac{w}{\varepsilon_c} c_6(t), \quad (7a)$$

$$c_4(t) = -\frac{\sqrt{2}w}{\varepsilon_c} c_3(t) - \frac{w}{\varepsilon_c} c_6(t), \quad (7b)$$

while states LL and RR are completely neglected since their contributions are very small (see Fig. 3). Substituting Eqs. (7) into the Schrödinger equation we reduce the system to an effective two-level system (TLS). The reduced two-dimensional equation has the form

$$i\frac{d}{dt}c_3(t) = (2\varepsilon_c + U_c - \frac{4w^2}{\varepsilon_c})c_3(t) - \frac{2\sqrt{2}w^2}{\varepsilon_c}c_6(t), \quad (8a)$$

$$i\frac{d}{dt}c_6(t) = -\frac{2\sqrt{2}w^2}{\varepsilon_c}c_3(t) - \frac{2w^2}{\varepsilon_c}c_6(t). \quad (8b)$$

Therefore, starting from the initial state CC , the subsequent evolution is featured by a coherent population transfer between the states CC and LR , just as shown in Fig. 3. In particular, when ε_c is modulated to satisfy the following equation:

$$2\varepsilon_c + U_c - \frac{4w^2}{\varepsilon_c} = \frac{2w^2}{\varepsilon_c}, \quad (9)$$

the coherent transfer will be complete—i.e., population probability of target state $|S^6\rangle$ can reach unity. The value of ε_c that satisfies Eq. (9) corresponds to the exact location of the avoided crossing shown in the inset of Fig. 2(b) and can be easily obtained:

$$\varepsilon_c = \varepsilon_c^0 = \frac{-U_c - \sqrt{U_c^2 + 16w^2}}{4}. \quad (10)$$

Correspondingly, the resonance frequency of the two states is given from (8) by

$$\omega_r = -\frac{2\sqrt{2}w^2}{\varepsilon_c^0} \simeq \frac{4\sqrt{2}w^2}{U_c}. \quad (11)$$

Thus the oscillation period of the population is given by

$$T = \pi/\omega_r \simeq \pi U_c/(4\sqrt{2}w^2). \quad (12)$$

The result of our two-state approximation is shown in Fig. 3 (dotted line). Clearly, in comparison with the exact numerical solution, our two-state approximation describes the system evolution very well. Therefore we arrive at the conclusion that at time given by Eq. (12), a sudden switch of gate voltage to another value will preserve the target state LR and spatially-separated spin entanglement comes into being. For a typical vertically-coupled semiconductor QD, the amplitude of U_c is about 5meV while $w \sim 0.05U_c$. Therefore from Eq. (12), the generation time of spatially-separated spin-singlet state is about 130ps, much shorter than the typical spin decoherence time of 100ns[21].

The above analysis shows that by a manipulation of the single-particle energy level of the central dot, there will be an avoided crossing in the energy spectrum, which reduces the system to an effective two-level system consisting of CC and LR . However, the preparation and preservation of the target state LR shown in Fig. 3(b) depends on a precise tailored switching of the resonant gate voltage. Any deviation may lead to significant errors. Moreover, a sudden switching of the gate voltage introduces high frequencies and therefore a population of higher-lying excited states. To overcome this shortcoming, a more practicable strategy for the experimental implementation of the above quantum state transfer process is the use of adiabatic passage: ε_c of the central dot is engineered to be near ε_c^0 and satisfies $\varepsilon_c < \varepsilon_c^0$. The initial state is engineered to be CC state. Then the gate voltage applied on the central dot will increase ε_c towards ε_c^0 . As demanded by the quantum adiabatic theorem, if the gate voltage increases infinitesimally slow the system will remain in its adiabatic state by transferring the two electrons from the central dot to the two side dots, forming spatially-separated spin-entangled state LR . The main leakage mechanism from the target state is due to the well-known Landau-Zener (LZ) tunneling. For the applied gate voltage scanning at a constant speed α , let us estimate the probability for LZ tunneling. Since we consider the problem with ε_c controlled around the avoided crossing of states CC and LR . Thus we assume that in the absence of the gate voltage, the single-particle energy level of central dot is given by ε_c^0 . Then in the presence of gate voltage, the energy level is given by

$$\varepsilon_c = \varepsilon_c^0 + eV_g = \varepsilon_c^0 + \alpha t. \quad (13)$$

Substituting Eq. (13) into Eq. (8) we obtain

$$i \frac{d}{dt} c_3(t) = \left(\frac{2w^2}{\varepsilon_c^0} + 2\alpha t \right) c_3(t) - \frac{2\sqrt{2}w^2}{\varepsilon_c^0} c_6(t), \quad (14a)$$

$$i \frac{d}{dt} c_6(t) = -\frac{2\sqrt{2}w^2}{\varepsilon_c^0} c_3(t) - \left(\frac{2w^2}{\varepsilon_c^0} + 2\alpha t \right) c_6(t), \quad (14b)$$

where we have neglected time dependence of the terms proportional to w^2/ε_c^0 . Eq. (14) is a standard expression for two-state LZ tunneling model, which gives the tunneling probability r

$$r = e^{-\frac{4\pi w^4}{\alpha(\varepsilon_c^0)^2}}. \quad (15)$$

To suppress the LZ tunneling, one can either increase the gap of the avoided crossing or decrease α such that the quantum state transition is in the adiabatic regime.

To illustrate this adiabatic passage process, we show in Fig. 4 the exact evolution of the probability of finding states CC and LR as a function of gate voltage for different values of the scanning rate α (solid lines). The initial state in these three panels is chosen to be the lower eigenstate on the left side of the avoided crossing shown in the inset of Fig. 2(b), which is dominated by the CC state. The inset of Fig. 4(a) shows the results with exact initial CC state. In the adiabatic case where α is very small, a complete $CC \rightarrow LR$ transfer occurs after the gate voltage cross the avoided crossing shown in the inset of Fig. 2, implying that the LZ tunneling is greatly suppressed. When the value of α becomes large, the LZ tunneling takes place partially and the outcome is a superposition of the states CC and LR . This is shown in Figs. 4(b)-(c). For comparison, we also plot in Fig. 4 the result of two-state approximation (14) (dotted lines). Clearly, our two-state approximation describes the LZ tunneling very well. It reveals in the inset of Fig. 4(a) that although the initial CC state is not the exact adiabatic state, the target state LR can be also produced with probability almost unity. This is the essential point of this paper.

We emphasize that the generation process of the spatially-separated spin singlet is dependent upon choice of initial state. The initial state chosen in this paper is CC . It is not the ground state of the Hamiltonian (3) when system parameters are engineered to be around ε_c^0 . In fact, from the evolution of the *exact* ground state shown in Fig. 5, one can see that when ε_c is around ε_c^0 , the ground state is a superposition of LC and RC , while the population of states CC and LR is near zero. Therefore the adiabatic evolution shown in Fig. 4 is not confined on the ground manifold. If one wants to transfer the initial CC state to the target LR state along the ground state evolution, as suggested by Saraga and Loss[14], then the quantum state will have to overcome a series of avoided crossings (see Fig. 2). Correspondingly, the final target LR state can only be reached via $LC \rightarrow LR$ and $RC \rightarrow LR$ transitions. Thus it will need a very long time to transfer the electrons to the LR state. Our approach, however, does not involve the participation of states LC and RC during system evolution. This is the essential distinction between our approach and that proposed in Ref. [14] (see Figs. 6 which plots generation process of spatially-separated entangled current by two approaches).

Although the CC state is far from the ground state structure when the value of ε_c is chosen to be near ε_c^0 and to satisfy $\varepsilon_c < \varepsilon_c^0$, this does not mean that it cannot be built up by the tunneling from the input lead into the central dot. In fact, when the first electron

tunnels into the central dot, due to the large energy mismatch between ε_c^0 and ε_s , this excess single electron cannot tunnel into the side dots. When the second electron tunnels into the central dot, the off-resonance condition ($\varepsilon_c < \varepsilon_c^0$) still ensures the prohibition of tunneling into the side dots. Thus the two electrons can be robustly purified and form a spin-singlet state CC , which is the first step of the entangler. Therefore we would like to say that, unlike a many-body system which always favors the ground state configuration, *the few-body QD system can be conveniently engineered to a localized state as a starting state due to its discrete energy spectrum property which prohibits diffusion to ground state.* After the initial CC state builds up, the next step is to adiabatically apply a gate voltage on the central dot, drive the system to target state LR as shown in the inset of Fig. 4(a). The final step is then to transport this spin-singlet state to the two output ports, forming a spatially-separated spin-entangled current. See Ref. [14] for details.

In summary, we have proposed a QD-based scheme for implementation of spatially-separated spin entanglement. By use of a triple quantum dot it becomes possible to prepare and preserve the spatially-separated spin-singlet via an efficient adiabatic passage method. The evolution of the system is restricted on an effective two-dimensional Hilbert space which consists of the initial state CC and the target state LR . Our approach, which is based on a combination of eigen-energy spectrum analysis and adiabatic elimination of dark states, may highlight the physical prospects in preparing entangled spin qubits in QD systems.

This work has been supported by NSF and MOST of China, and by US-DOE.
